Abstract: In this work, we investigate the electrospray technique for the preparation of graphene layers for use in chemiresistive gas sensors. A dispersion of reduced graphene oxide (rGO) in isopropyl alcohol (0.1 mg/mL) is electrosprayed and the rGO flakes are deposited onto a polymeric substrate with printed interdigitated electrodes. The surface area of the substrate covered with rGO is mainly determined by the distance between the needle and the substrate, while the rGO deposition pattern strongly depends on the flowrate and the applied voltage. Homogeneous layers of rGO are obtained in a stable cone-jet regime, and the room temperature detection behavior of the sensors towards NO_2, O_3 and CO is assessed. The sensors were not capable of detecting CO (up to 5 ppm), but they detected 0.2 ppm NO_2 and 0.05 ppm O_3. The results are encouraging regarding the use of electrospray for the production of low-cost and low-power gas sensors based on graphene for air quality applications.

Keywords: reduced graphene oxide; electrospray; deposition pattern; chemiresistive sensor; air pollutants

1. Introduction

A chemiresistor is the most widely used configuration of gas sensors. In chemiresistive sensors, gases are detected by measuring the changes in the electrical resistance of sensing layers induced by the adsorption of the gas molecules. In commercial chemiresistive sensors, the sensing layer is a thick or thin film of a metal oxide semiconductor (MOS) deposited onto a silicon or ceramic substrate with metallic electrodes and a resistor micromachined on its surface. The latter allows for heating the sensing layer to a high temperature dependent on the nature of the gas to be detected, in general above 300 °C. MOS gas sensors are produced by means of cost-intensive technologies used in microelectronics and surface coating industries (e.g., silicon micro-machining, sputtering, laser ablation or chemical vapor deposition), which commonly involve multistep, slow, and complex processes (e.g., lithography and etching) under extreme conditions (e.g., high vacuum and high temperature) [1]. Moreover, the power consumption of MOS gas sensors is high, typically tens of mW, due to the high working temperatures. The rapidly growing demand for miniaturized,

low-cost, and low-power sensors for use in portable and wearable devices and systems for a broad spectrum of applications (e.g., air quality monitoring in smart cities) is driving the development of novel materials showing outstanding gas sensing performance at ambient temperature such as nanostructured MOS, conductive polymers and carbon-based materials, which can be supported on affordable substrate materials like plastic, paper or fabrics [2–4].

Graphene comprises a family of materials, namely pristine graphene (PG), graphene oxide (GO) and reduced graphene oxide (rGO), which are being intensively investigated for trace gas/vapor sensing at room temperature because of their high surface-to-volume ratio, specific surface area, charge carrier mobility, and chemical activity at defect sites, as well as for their unique band structure and tunable defect density [5–10]. Pure defect-free PG possesses high electrical conductivity and low intrinsic noise but is very inert due to the absence of hanging bonds on its surface and edges, as required for gas adsorption, and needs to be functionalized with polymers, metals or other modifiers. In addition, the methods currently used for the production of PG are costly and hazardous, not suitable for mass production and do not allow for a good control of the final product. A cost-effective method to produce graphene in large quantities is to firstly produce GO by the oxidative exfoliation of graphite in a liquid phase and to subsequently reduce it by chemical or thermal means to obtain rGO. The low conductivity of GO, dependent upon the degree of oxidation, is a clear disadvantage, whereas the abundance of oxygen-rich functional groups on its surface makes GO very reactive and, hence, a potentially promising candidate for gas sensing. Finally, rGO has proven advantages over PG considering the low production costs, fine-tuning of structure and properties such as electrical conductivity, dispersal in water, and the ease of surface modification and functionalization [11–16]. A drawback of graphene materials containing oxygen groups is that these strongly interact with reactive adsorbates, acting as higher-energy binding sites and limiting reversibility and repetitive use of graphene-based gas sensors. This limitation can be overcome by means of UV irradiation. It has been proved that UV light accelerates gas desorption from nanostructured MOS, graphene and other emerging 2D materials suitable for gas sensing at room temperature, and can also enhance sensor sensitivity and selectivity to specific gases [17–20].

Printing technologies are promising routes for the production of micro/nano-devices because they allow for processing diverse electronic materials compatible with flexible/bendable substrates without involving extreme conditions, complex processes and/or costly equipment [21–23]. Inkjet printing (IJP) is the most commonly used method for the research and development of functional material-based devices due to the ease of prototyping, large surface area coverage, and scalability for mass production. The inkjet print-head uses a short pressure pulse generated either thermally or piezoelectrically to expel one or more liquid droplets (~100 pL) of a colloidal suspension out of a micrometers-sized nozzle (30–60 μm). IJP allows for producing versatile micro/nano-films with no need of masks, stencils or templates; on-demand digital printing in areas only where the material needs to be deposited; and multiple layers with well-controlled material deposition and good precision. The major limitation of IJP is the narrow value range that ink properties (e.g., viscosity, surface tension, particle size, and particle concentration) must fall within for consistent droplet formation and pattern printing. The creation of a homogeneous film with constant thickness using IJP is a challenge due to the tolerance of the nominal droplet volume and the accumulation of material at the edge of the printed structure due to the evaporation gradient, so called "coffee ring" effect. The IJP resolution is also typically limited to micrometers, since thermal and piezoelectric actuators are unable to dispense droplets smaller than the droplet size. Finally, IJP is one of the slowest printing techniques due to the requirement of the print-head to scan the substrate. The printing speed can be increased by employing a greater number of nozzles, reducing the amount of movement required to build the pattern, potentially reaching speeds of 10 m/min. IJP has been successfully applied to the deposition of thin films of graphene and graphene-metal, -metal oxide, and -polymer nanocomposites onto rigid and flexible substrates for use in chemiresistive gas sensors [24–29].

Electrospray (ES) has gained interest for the production of low-cost micro/nano-devices because of its capability to create thin films of a high quality with more precise control of the film

properties compared to other printing techniques [30–32]. In an ES system, a liquid with sufficient electrical conductivity is fed at a constant rate (0.5–50 µL/min) through a capillary tube (30–300 µm) that is charged at high potential relative to a nearby ground electrode. On the tip of the capillary tube the liquid meniscus takes a conical shape with a fine jet issuing from the cone apex. Varicose waves on the surface of the jet lead to the jet breaking up into small highly charged droplets, which, due to Coulomb repulsion, are radially dispersed. Clogging is generally not an issue for ES even with suspensions of high particle concentration because the bore is typically two orders of magnitude larger than the jet/droplet diameter. Another key feature of ES is the quasi monodispersity of the droplets. The capability of producing monodisperse droplets with relative ease is unmatched by any other droplet generation scheme, especially in the submicron range. ES is capable of achieving an extremely high resolution, down to 1 µm, overcoming the resolution limitation of IJP. To achieve this, however, a much smaller nozzle is required, and the construction of micrometer and sub-micrometer-sized metal-coated nozzles with a high consistency involves a certain complexity and intricacy. In addition, very dilute inks need to be used to avoid nozzle clogging. The major ES drawback is the low flow rate at which the cone-jet can be established. This drawback has been addressed through multiplex ES (MES) techniques, demonstrating the simultaneous operation of hundreds of ES sources and a remarkable packing density exceeding 10^4 sources/cm^2 [33]. Thin films of MOS and conductive polymers have been prepared by the ES of precursor solutions or nanoparticle suspensions for gas sensing applications [34–39]. Only recently has ES received attention for the preparation of gas sensors based on graphene [40,41].

In this work, we explore the feasibility of electrospray for the preparation of graphene films for gas sensing. For that purpose, we choose commercial graphene (rGO) and characterize the deposits of electrosprayed rGO in terms of surface coverage area and deposition pattern in dependence of the main electrospray parameters; these are the needle–substrate distance, flowrate and applied voltage. Moreover, we characterize the performance of the electrosprayed rGO films for detecting NO_2, O_3 and CO in levels relevant to air quality applications.

2. Materials and Methods

2.1. Reduced Graphene Oxide

We use rGO powder (E800, Abalonyx AS, Oslo, Norway) produced by a modified Hummer's method followed by thermal reduction of GO at 800 °C. The manufacturer provided the values of the specific surface area (436 m^2/g), electrical conductivity (20 S/m) and carbon-to-oxyxgen atomic ratio (35) of the rGO. Raman spectroscopy was used to analyze the quality of the rGO. The Ramam spectrum of monolayer defect-free graphene exhibits a relatively simple structure with two bands, G and 2D, with peak intensities at λ~1587, 2679 cm^{-1}; the peak intensity ratio I_G/I_{2D} is 0.5; and the 2D band is a single symmetric peak with a full width at half maximum (FWHM)~30 cm^{-1} [42]. As can be seen in Figure 1a, the Ramam spectrum of the rGO used here deviates from that previously described. Both G and 2D bands are shifted towards higher wavelength numbers (λ~1637, 3448 cm^{-1}), which is mainly attributed to the effect of the substrate supporting the rGO sample. Moreover, the peak intensity ratio is lower (I_G/I_{2D}~0.3), and the 2D band is not fully symmetric and much broader (FWHM~170 cm^{-1}) than for monolayer graphene. These results reveal that the rGO is multilayer graphene [42,43]. The peak observed at λ~1383 cm^{-1} corresponds to the D band of graphene, which is a measure of the level of disorder or defects in the material. The low intensity of the D band with respect to the G band indicates that the rGO is highly ordered [44]. X-ray diffraction (XRD) examined the crystallinity of the rGO. In Figure 1b, the peak at 2θ~26.52° matches the position of the crystal phase (002) for graphite, but the broader peak for rGO implies that the phase (002) is arranged randomly as compared to the high crystallization structure of graphite. The poor arrangement may be due to the formation of single or a few layers of rGO after reduction from GO. The interlayer spacing given by Bragg's law is 0.3373 nm, and the thickness of the rGO calculated by using Scherrer's equation and the FWHM of the (002) peak reaches 2.33 nm. Thus, the average number of layers in the stacked multilayer rGO is 7. These results are consistent with those reported

by other authors for rGO produced by the same method [45,46]. Finally, Fourier transform infra-red spectroscopy (FTIR) provided information about the functional groups in the rGO. Figure 1c evidences the presence in the rGO of bond hydroxyl groups –OH (λ~1380, 3460 cm^{-1}), epoxy groups C-O-C (λ~1000, 1130 cm^{-1}), and to a lesser extent also carboxyl groups –COOH (λ~1740 cm^{-1}) [43–45].

2.2. Sensor Preparation

Sensors are prepared by the electrospray of a liquid suspension of rGO and subsequent deposition of the rGO flakes from the gas phase onto a substrate. The electrospray system and the substrate are depicted in Figure 2. The electrospray setup is arranged horizontally and its main components are a syringe pump (SyringePump® NE-1000, New Era Pump Systems Inc, Farmingdale, NY, USA) and a high voltage supply (Ioner® HV-7020, RAMEM SA, Madrid, Spain). The rGO suspension is delivered through a stainless steel needle (Neolus® NN-2525R, Terumo Europe NV, Leuven, Belgium) with a straight cylindrical tip of 300 μm in inner diameter, and a CMOS camera (DMK 23UP1300, The Imaging Source Europe GmbH, Bremen, Germany) allows for visualizing and recording the liquid that comes out from the needle tip. The substrate (Eurocuircuits NV, Mechelen, Belgium) is a circular plate of a diameter of 15.24 mm and a thickness of 1.55 mm. The base material is a polymer (FR4IMP) commonly used in printed circuit boards (PCBs) with 4 interdigitated electrodes (IDEs) of copper on its upper surface. The interdigital gap length is 0.1 mm and the surface area of the IDEs is 7.3 mm^2. The latter is the active area that is coated with the sensing material.

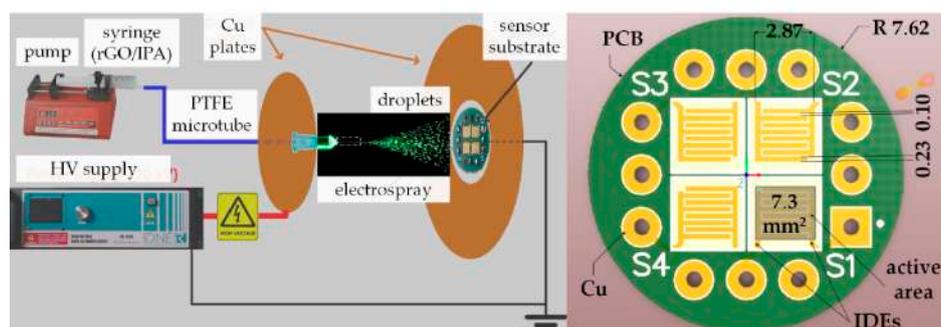

Figure 2. (**Left**) Sketch of electrospray setup. (**Right**) Draw of sensor substrate (dimensions in mm).

Suspensions are prepared by pouring the rGO powder in a liquid and dispersing the rGO flakes in the solvent through ultrasonic agitation. It was necessary to optimize the solvent, the concentration of rGO and the ultrasonication time to ensure a high degree of dispersion of the rGO flakes in the suspension. Moreover, the dispersion must be stable to prevent logging of the capillary tube or the needle during sensor preparation. We do not use either surfactants or dispersants so as not to alter the gas sensing performance of the rGO. Finally, highly volatile solvents are preferred, since they rapidly and fully evaporate from the droplets, and only the rGO flakes reach the substrate. After testing different solvents (e.g., deionized water, ethanol, isopropanol, acetone and ethylene glycol), we chose isopropyl alcohol (IPA) as the most suitable solvent for dispersing and electrospraying the rGO, and set the concentration of rGO in the suspension to 0.1 mg/mL. An optimal rGO dispersion was attained after one hour of sonication, and the dispersion remained stable (i.e., agglomeration of rGO flakes was not observed by the naked eye either in the syringe or in the capillary tube) for nearly half an hour.

2.3. Sensor Characterization

We characterized the sensing performance of the sensors based on electrosprayed rGO towards air pollutants such as NO_2, O_3 and CO. We used calibration cylinders of gas mixtures of NO_2 and CO in dry air, and mixtures of O_3 in dry air were generated by using an ozone generator based on a UV lamp (UVP SOG-1, Thermo Fisher Scientific Inc, Waltham, Massachusetts, USA) and an air cylinder. Figure 3 shows the facility used for sensor measurements with mixtures of ozone and air.

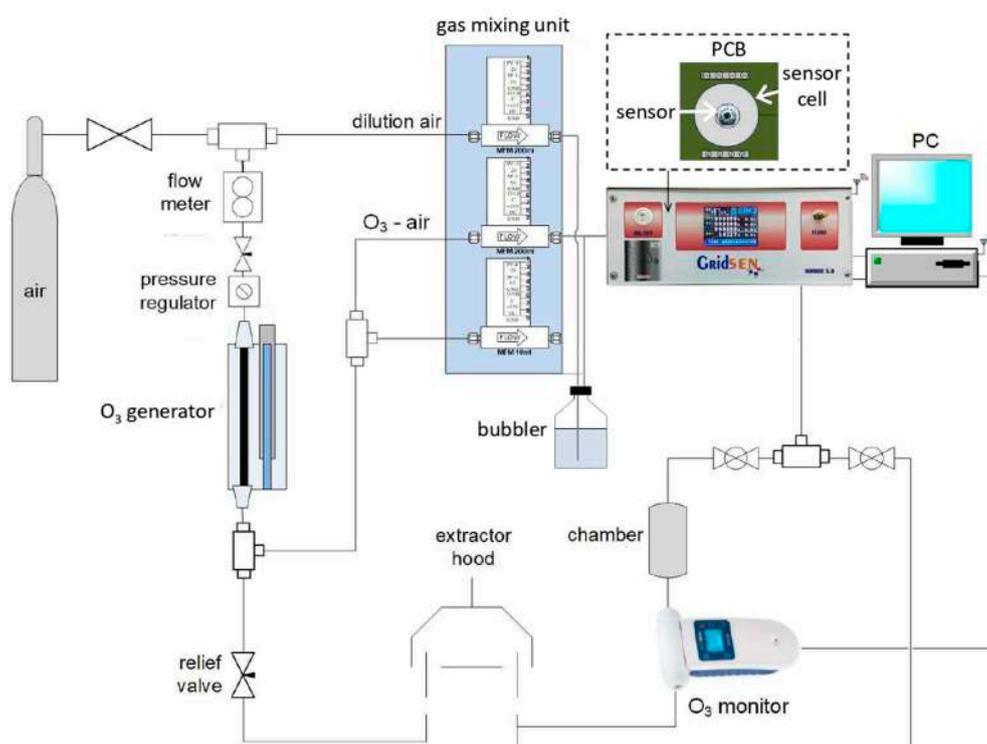

Figure 3. Layout of the facility used to characterize sensor detection performance towards ozone.

In the gas mixing unit (GMU-06, Ray Ingeniería Electrónica SL, Cáceres, Spain), the mixture of O_3 and air from the ozone generator is diluted with dry air from the cylinder. Optionally, water is added to the gas by flowing the gas stream through a bubbler and, then, the gas mixture enters the sensor cell. The gas flowrate is 0.2 L/min and the concentration of O_3 in the gas is measured downstream of the sensor cell by an ozone monitor including a semiconductor gas sensor (S500 and OZL, Aeroqual Ltd, Auckland, New Zealand). The sensor cell has a free volume of 0.58 cm^3 and temperarute and humidity sensors are placed on its top wall to continuously monitor the conditions

inside the cell. The facility is fully automated and controlled by means of a program based on the LabView software.

3. Results

3.1. Electrospray Regime

Figure 4 shows images of the liquid that comes out of the nozzle during the electrospray of the rGO dispersion prepared as described in Section 2.2. The images were obtained by setting the distance between the needle and the substrate and the pump feedrate and increasing the applied voltage.

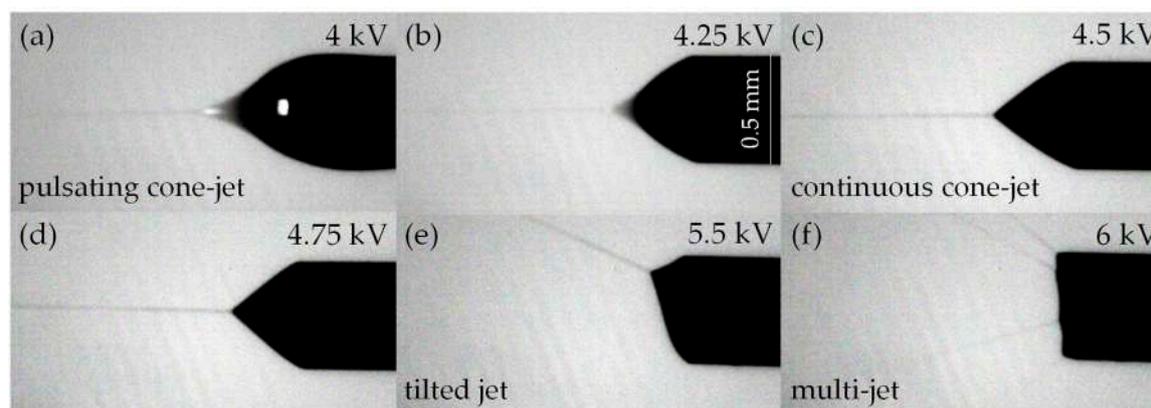

Figure 4. Camera pictures of the electrospray of a dispersion of rGO in isopropyl alcohol (0.1 mg/mL) with increasing applied voltage (needle–substrate distance: 15 mm, flowrate: 5 µL/min). The electrospray cone-jet mode evolves from an unstable pulsating regime (**a**) towards a stable continuous regime (**c**). Then, it enters again in unstable mode (**d**,**e**) and ends with the disintegration of the liquid meniscus in multiple jets (**f**).

The different electrohydrodynamic jetting modes observed in Figure 4 have been extensively investigated [47–50]. In general, the liquid meniscus narrows and elongates under the action of the surface tension and the electric field, and, at a critical voltage, a (Taylor) cone is formed. With a further increase in the electric field, the cone becomes unstable and a very thin jet (small and thin compared with the capillary diameter) is emitted from the cone apex. A pulsating cone-jet mode appears, the pulsation frequency of which decreases with the increasing voltage, and, at the same time, the concavely shape cone observed in the pulsation mode (a) changes to a nearly straight cone in the continuous cone-jet mode (c). A complex transition into a stable regime exists between a pulsating and continuous cone-jet regime. Moreover, a complex jetting behavior, such as tilted jets (e) and multi-jets (f), is shown at higher electric field strenghts.

3.2. Deposition Pattern

We performed electrospray deposition tests varying the distance between the needle and the substrate (6–30 mm). After setting the needle–substrate distance, the flowrate and the voltage are adjusted until the cone-jet mode appeared and no liquid deposits on the substrate. Then, electrospray deposition is conducted for different values of the applied voltage and deposition time (5–20 min). After the tests, the rGO deposits formed onto the substrate are observed with an optical microscope (EM7-5TR, Meiji Techno Co, Saitama, Japan) and pictures are taken by a digital camera connected to the microscope.

Figure 5 displays images of the rGO deposits found on the substrates when the electrospray operates in the stable cone-jet mode. Then, the rGO forms circular spots on the substrate and the diameter of the spot decreases with the decreasing distance between the needle and the substrate. For distances larger than 15 mm, the needle was centered in the circular substrate, whereas, for distances less than 15 mm, the needle was centered in the square IDEs. Figure 5c,d correspond to the

tests in which the needle–substrate distance was set to 15 mm and the needle pointed to either the center of the substrate or the center of the IDEs, respectively. It is observed that the rGO is fairly homogeneously distributed over the area of the deposits, particularly for the small spots in Figure 5e,f, the area of which is comparable to the active area of the sensor.

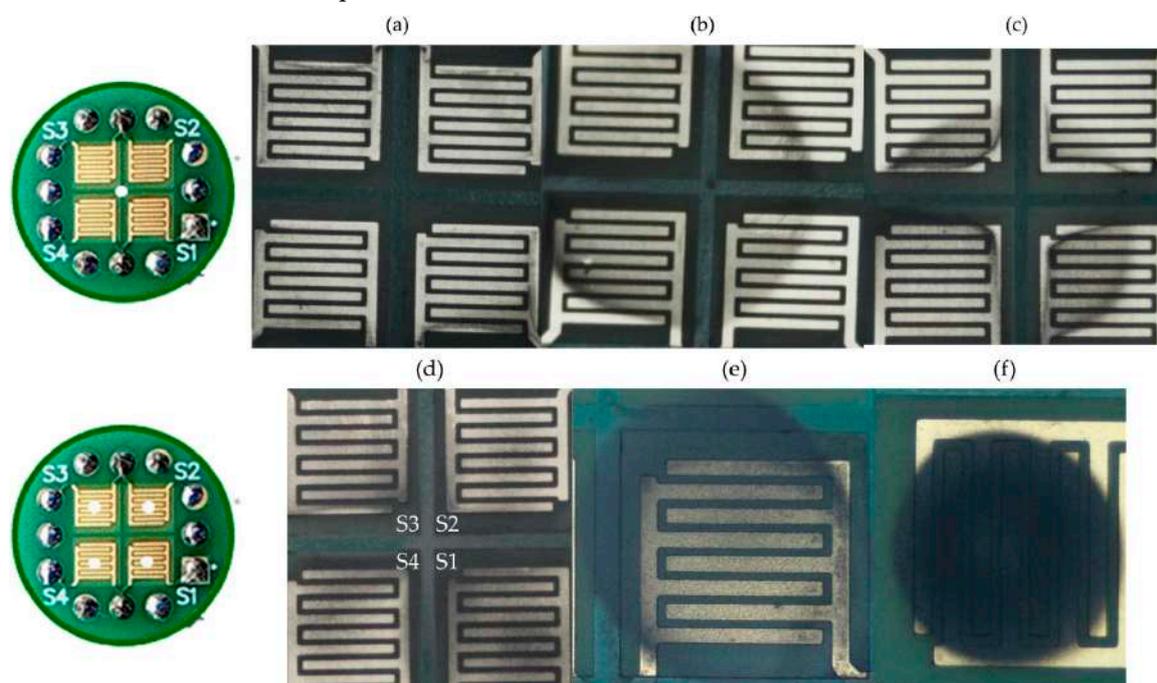

Figure 5. Camera pictures of rGO deposits obtained by electrospray of a dispersion of rGO in isopropyl alcohol (0.1 mg/mL) with the needle pointing to the center of the substrate (**a**–**c**) and to the center of the interdigitated electrodes (**d**–**f**). Needle-susbtrate distance, flowrate, voltage, and deposition time: (**a**) 30 mm, 8 μL/min, 5.5 kV, 15 min; (**b**) 25 mm, 6 μL/min, 5 kV, 20 min; (**c**) 15 mm, 4.25 kV, 7 μL/min, 10 min; (**d**) 15 mm, 5 μL/min, 4 kV, S1 and S3: 10 min, S2 and S4: 5 min; (**e**) 12 mm, 5 μL/min, 4.15 kV, S1:10 min; (**f**) 7 mm, 3 μL/min, 2.7 kV, S1:15 min.

3.3. Gas Detection

We characterized the detection behaviour of the sensors based on electrosprayed rGO towards NO_2, O_3 and CO. To illustrate that, we choose the sensors displayed in Figure 5d. Gas measurements were also conducted with the sensors in Figure 5a–c, but they showed a poorer performance: the resistance was out of the measurement range, the sensor response was very low and/or the signal to noise was unacceptable. No measurements have been performed yet with the sensors in Figure 5e,f. Sensors were exposed to mixtures of NO_2, O_3 or CO in air followed by clean air, at room temperature and variable relative humidity (RH), between 5% and 60%. The concentration of the target gas varied in the range of 0.05 to 0.3 ppm (NO_2, O_3) and 0.5 to 5 ppm (CO). The rGO behaved like a *p*-type semiconductor towards NO_2 and O_3 and was not able to detect CO in levels of up to 5 ppm.

Figures 6 and 7 show the dynamic resistance and the response of the sensors in Figure 5d during the tests with mixtures of NO_2-air and O_3-air, respectively. The sensor response is defined as

$$Res(\%) = \frac{|R_g - R_a|}{R_a} \cdot 100 \tag{1}$$

where R_g and R_a stand for the resistance of the sensor exposed to the target gas, at the end of the detection phase, and the resistance of the sensor exposed to clean air, at the end of the recovery phase, respectively. As can be observed, the sensors are more sensitive to O_3 than NO_2, and the response to both gases increases with the increasing air humidity. At 20% RH, the sensor response to 0.05 ppm O_3 exceeds 1%, whereas that response level is reached only at 0.2 ppm NO_2.
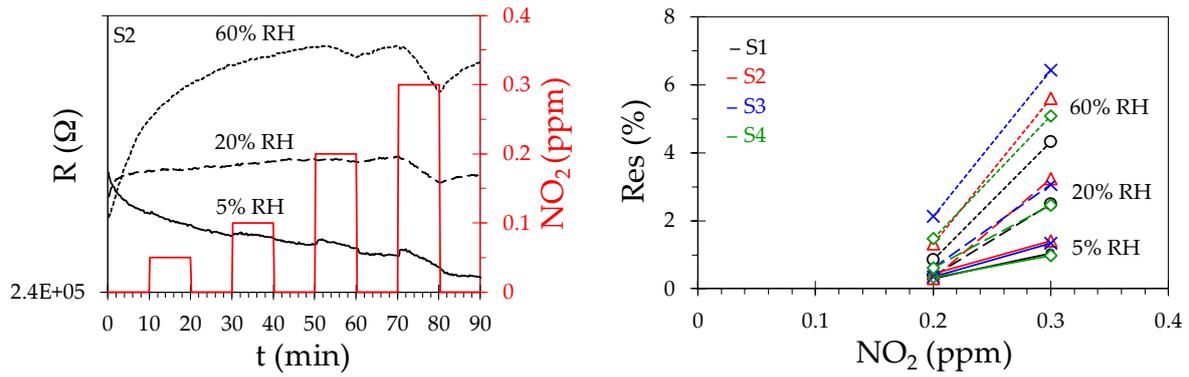

Figure 6. Dynamic resistance (**left**) and response (**right**) of sensors based on electrosprayed rGO under exposure to mixtures NO2-air with different NO2 concentrations and relative humidity levels.

Figure 7. Dynamic resistance (**left**) and response (**right**) of sensors based on electrosprayed rGO under exposure to mixtures O3-air with different O3 concentrations and relative humidity levels.
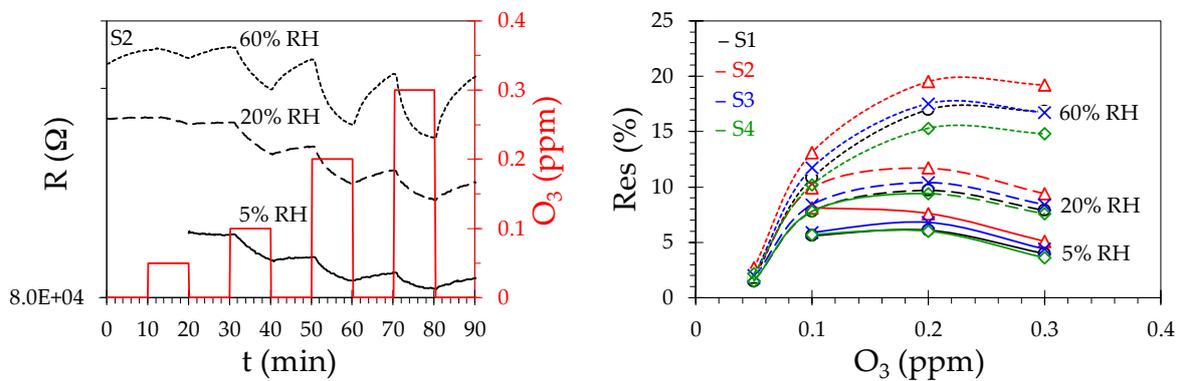

The sensor recovery time decreases with the increasing content of water in the gas. At 60% RH, the sensor resistance approaches the reference value R_a after 10 min of exposure to clean air. We attempted then to activate gas desorption from the rGO layer by irradiation with UV light. For that purpose, we installed a UV-LED light source (OCU-1400 UB355, λ~355 nm, Osa Opto Light GmbH, Berlin, Germany) centered on the upper wall of the sensor cell, at a distance of approximately 1 cm from the sensor surface. As an example, Figure 8 shows the results obtained when the sensors were exposed to clean air, after exposure to 0.1 ppm O3 in air with 20% RH. The sensors returned to the baseline resistance after 4 min of irradiation with UV light.

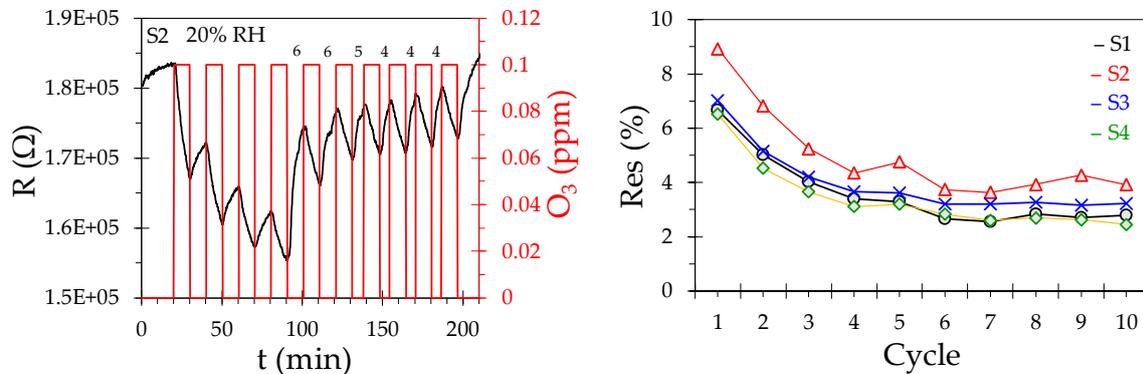

Figure 8. Dynamic resistance (**left**) and response (**right**) of sensors based on electrosprayed rGO under exposure to a mixture of O3 and air (0.1 ppm O3, 20% RH). After 90 min (cycle 4), sensors are irradiated with UV light for gas desorption during 6 min (cycles 4 and 5), 5 min (cycle 6) and 4 min (cycles 7, 8 and 9).

4. Discussion

In this this work, we prove the feasibility of electrospray for the preparation of graphene films for gas sensing applications. We have been able to produce rather uniform graphene films over a wide range of areas (7–100 mm^2) by the electrospray of an rGO dispersion, operating the electrospray in continuous cone-jet mode and varying the distance between the needle and the substrate. Nonetheless, the deposition pattern of graphene is strongly sensitive to the value of the applied voltage and small deviations from the ideal voltage (i.e., stable cone-jet mode) leads to highly inhomogeneous deposits that in some cases exhibited well-defined and reproducible patterns (e.g., circular or ellipsoidal rings). In the future, effort will be devoted to the preparation of homogeneous graphene layers for miniaturized sensors of active area below 1 mm^2, which can be attained by using nozzles of diameters ≤0.1 mm and nozzle-substrate distances ≤1 mm.

The rGO used in this work shows good sensitivity to oxidizing gases such as NO_2 and O_3, but is insensitive to a reducing gas such as CO. Sub-ppm levels of NO_2 (0.2 ppm) and O_3 (0.05 ppm) in air have been detected at room temperature by sensors based on rGO films with average surface load of a few μg/mm^2, but the sensor recovery time is unacceptably long for practical applications Similarly long recovery times (>5 min) have been reported for rGO sensors prepared by different techniques after exposure to a few ppm NO_2 [51–53]. To the best of our knowledge, this is the first work that studies the capability of rGO sensors to detect O_3. Further work will focus on the dependence of the sensor sensitivity on the rGO load and on the effect of the wavelength and intensity of the UV light on the sensor recovery time.
